Abstract

This study investigates the determinants of player market value in elite European football using a cross-classified multilevel model applied to 7,023 observations between 2013 and 2024. By disentangling individual reputation from club context, we identify distinct non-linear trends in market evolution and biological aging. Our results reveal a “Boom and Bust” market cycle, a strict “Inverted-U” career arc peaking at age 27, and a significant 42% valuation premium for key starters (“Squad Status”). Furthermore, we find evidence of a “Diversity Premium,” where clubs with higher international representation garner higher player valuations, contrasting with a “Domestic Discount” for local players.

Keywords: football economics, multilevel modeling, player valuation, club prestige, UEFA coefficient, sports analytics

1 Introduction and Research Motivation

The valuation of elite athletes in the European soccer transfer market has evolved from a subjective scouting exercise into a global financial industry exceeding €7 billion annually. In this high-stakes environment, accurate valuation is critical for club solvency and competitive balance. In this study, we operationalize market value using crowd-sourced estimates from Transfermarkt. This metric has been widely validated in sports economics literature as a robust proxy for actual transfer fees and serves as a leading indicator of player market valuation based on demand.

Foundational research in sports economics has long sought to isolate the determinants of this value. Frick (2007) established that while hard performance metrics like goals and assists are primary drivers, valuation follows a strict inverted-U biological trajectory, typically peaking between ages 27 and 28 before depreciating rapidly. Beyond on-pitch performance, Franck and Nüesch (2012) empirically demonstrated the superstar effect. They found that non-performance factors such as media popularity and brand visibility can magnify a player’s value significantly, especially at the top end of the wage distribution. However, these existing studies often model players as static units nested within a single club. This approach fails to account for the dynamic reality of modern football, where players transfer between teams and accumulate value from both their portable human capital (such as experience and age) and the institutional prestige of their current employer. Neglecting this cross-classified structure, where player and club effects intersect rather than nest, likely misestimates the true drivers of market value. We address this methodological limitation by applying a cross-classified multilevel model to a decade of transfer data (2013

to 2024). By disentangling individual reputation from club context, we aim to answer four critical questions that remain under-explored in nested models:

1. **Market Evolution (RQ1):** How has the transfer market evolved annually compared to the 2013 baseline? We believe that understanding the nonlinear trajectory of market inflation is essential for distinguishing real player value growth from sector-wide inflation.
2. **Biological Career Arc (RQ2):** How does market value change as a player moves through their career? By modeling the nonlinear effect of age, we aim to validate Frick’s (2007) peak age hypothesis and identify the precise window where physical peak and experience intersect.
3. **Squad Status (RQ3):** Does playing more minutes than the average teammate serve as a primary driver of valuation? While goals capture output, they bias towards attackers. We propose that squad status (measured by relative minutes played) is a more universal signal of manager trust and player utility across all positions.
4. **Contextual Premiums (RQ4):** Is there a premium for club diversity and a discount for domestic players? As the labor market globalizes, we investigate whether clubs with broader international recruitment generate higher valuations and whether domestic players face a valuation discount compared to imported talent.

2 Method

Data Source. We obtained data from [Transfermarkt](#) and [Union of European Football Association](#) (UEFA) official rankings, which are both publicly available websites. At the time of this study, Transfermarkt does not have free API access to their data repository. Instead, the R package [worldfootballR](#) allows us to scrape data from their website. However, there are several limitations to this package such as timeout requests and failure to capture dynamic JavaScript tables on webpages. Fortunately, we found the necessary data through Kaggle [Football Data from Transfermarkt](#), which allowed us to focus on the modeling aspect of this project following data restructuring and predictor variable engineering.

Sample Characteristics. We used the 10-year averaged UEFA coefficient rankings¹ to select the top 21 European soccer teams as our first stage sampling. In our second stage nonrandom sampling, we selected soccer players that played for a full season in one of the 21 clubs from 2013 to 2024. This resulted in 2,215 male players representing 7,168 seasons. However, after examining missing data (which mostly came from missing information on citizenship status), we were left with 2,159 players representing 7,023 seasons. This represents a 2.5% loss of player data and a 2% loss in season data. The majority of players across clubs and years were in their mid-20s ($M = 26.5$, $SD = 4.6$). In this sample, players on average played 3.2 ($SD = 2.9$) seasons. If we were to drop players that had less than two seasons to examine player trajectories, we would lose 62% of our sample. Figure 1 shows the number of players in each of the 21 clubs across the years.

¹UEFA coefficient rankings are a points-based system used by European football’s governing body to rank national associations and clubs based on their performance in European competitions, which determines qualification spots and seeding for tournaments like the Champions League and Europa League.

Figure 1. On Average Each Team Contains about 30 Players Per Season

Variable Selection and Normalization. Our outcome of interest is a player's yearly market valuation, which we convert from euros to US dollars. Market valuation in euros varies by month, so we first calculated the yearly average for each player prior to transforming to USD. We log-transform market value to 2024 USD because financial data follows a Pareto distribution rather than a normal distribution. Keeping the outcome on the raw scale would result in extremely large residuals for high-value players and small residuals for low-value players, which violates the assumption of homoscedasticity. Log-transforming the outcome compresses the extreme outliers by pulling the long right tail to make the distribution more normal. Therefore, this adjustment allows us to compare the real economic power of a player in 2013 versus 2024 without the noise of currency fluctuation.² Figure 2 shows

²We handle exchange rate fluctuation by using historical exchange rates to convert our values to USD. We also adjust market value to 2024 USD because 10 million dollars in 2013 is not the same as 10 million

that market value has substantial variability across years, yet most values are at the lower end, which is common for salary data. When we log-transform our outcome, we bring the lower values up and the higher values down.

A list of variables we used for modeling players’ market values are shown in Table 1 alongside how and why they were centered. THIS TABLE MIGHT NEED TO GO IN The Appendix.

To ensure meaningful model intercepts and convergence, we applied the following centering strategies:

- **Outcome:** We used the natural log of inflation-adjusted market value in 2024 due to inflation. By keeping the raw values, we would lose information about real economic value.

(`usd_revenue_2024_log`).

- **Time:** We centered season year at the minimum value, making 2013 equal to 0 (`season_year_c`).
- **Player Traits:** We applied grand-mean centering to age (`age_c`) and height (`height_c`).
- **Squad Status:** We standardized minutes played (Z-score) relative to each specific club-year. This isolates a player’s status as a starter or bench player relative to their current teammates and removes the noise of team-level rotation policies.
- **Club Context:** We grand-mean centered the proportion of foreign players (`foreign_players`).
- **Categorical Controls:** We included region, position, and citizenship status (coded as 1 for citizens of the club country).

Table 1: Table 1. Data Structure for fixed effects, except year as it is a random slope

		Centering Strategy/	
Variable Type	Variable	Form Factor	Justification
Time	Season Year	Min-Centering (+	Establishes a
		Quadratic)	meaningful starting intercept (2013 =0)
Contextual, Club	UEFA Coefficient	Year-Mean	Isolates relative
		Centering	prestige; removes historical inflation

Centering Strategy/			
Variable Type	Variable	Form Factor	Justification
Player Characteristics	Foreign Players	Grand-Mean	Moves baseline to
	Proportion	Centering	“Average Club” (since 0% is unlikely)
	Age	Grand-Mean (+	Captures absolute
		Quadratic)	career stage (Prospect → Prime → Veteran)
	Height (in cm)	Grand-Mean	Captures premium for absolute physical size
Player Demographic	Position	Reference group, attacker	Attackers tend to be valued more on average
	Citizen of Club	None (Raw binary	Keeps “Non-Citizen”
	Country	0/1)	as clear reference group. Separates individual status from club composition (foreign_players)

Centering Strategy/			
Variable Type	Variable	Form Factor	Justification
Player Performance	Region of origin	Reference group, Europe	Control variable for where player is from
	Goals	Position-Centering	Preserves natural 0 and marginal value of 1 goal interpretation
	Assists	Position-Centering	Preserves natural 0 and marginal value of 1 assist interpretation
	Red Card	raw season count	Meaningful 0 interpretation
	Yellow Card	raw season count	Meaningful 0 interpretation
	Average minutes played in season	Year-Mean	Isolates whether player is a starter or bench player
		Centering, z-score	

Data Assumptions: We assume that variables such as height and positions are time invariant for the duration of this study. At the club level, we assume mutually exclusiveness in that players can only belong to one club in a given year. Although a player could have switched clubs mid-season, we keep this constant for model simplicity. We also assume that the

relationship between age and log-market value is non-linear and parabolic so we introduce a quadratic term on age. Because we excluded observations with missing data (listwise deletion), we assume the data are Missing Completely at Random (MCAR) or that the proportion of missing cases ($\sim 2\%$) is negligible and does not introduce systematic bias.

3 Modeling Approach

We employ a cross-classified multilevel linear model to partition variance across observations (Level 1), players (Level 2a), and clubs (Level 2b). This structure explicitly accounts for players transferring between clubs and thus treating player and club as cross random factors rather than a strict three level hierarchy. We found that in this sample, almost 20% of players had been in two to seven (17% in two clubs) clubs which was the basis for fitting a cross-classified model to these data. Figure 3 is a visual of a cross-classified model example of three players that either move through clubs or remain in the same club throughout their career. Players can change teams over their span of their careers meaning that the player context can change. They may be a star player in one team and a bench player on a different team that they switch to. In a cross-classified model, the player is the constant unit (i), but the club (j) changes over time (t). If player (I) plays for club (j1) in year (t0) but switches to club (j2) in year (t1) the fixed effect in the model, such as minutes played, updates the players status, as opposed to having static or average predictors. Club attributes, such as foreign players and UEFA scores, ensures that when player move clubs,

the model swaps the values of X_{j1} , for X_{j2} . Player's characteristics, for instance age and height, move with the player across time.

Figure 1: Figure 3. Cross-Classified Data Structure: Players move between clubs over time.

Jianing, can you write this result? This section should be for the slope, but remember that the slope is on the club not player.

Figure 4.a. Individual Systolic Blood Pressure (SBP) Trajectories

Blue line: Average time point Market Value

Figure 4.b. Sample Average Systolic Blood Pressure (SBP) Trajectories

Figure 4.b. Sample Average Systolic Blood Pressure (SBP) Trajectories

We plot age by yearly market value in 2024 USD (on the log scale) in Figure 5. for each team and observe almost an upside down u shape. As players get older you are valued less in the market, same for younger players.

Figure 5: Age and Market Value (log) follow a Quadratic Relationship

3.1 Model Specification

To formally describe our analysis, we utilize a hierarchical notation system that decomposes the model into observation, player, and club levels. This analysis clarifies how the cross-classified structure (i players crossed with j clubs) contributes to the variance in market value.

Level 1: Observation Model (Time-Varying Effects)

At the observation level (time t , player i , club j), the log-transformed market value is a function of a player-club specific intercept (π_{0ij}), temporal trends, biological aging, and dynamic performance metrics:

$$\begin{aligned} \log(\text{Revenue})_{tij} = & \pi_{0ij} \\ & + \pi_{1j}(\text{Year}_t) + \pi_2(\text{Year}_t^2) + \pi_3(\text{Year}_t^3) \\ & + \pi_4(\text{Age}_{it}) + \pi_5(\text{Age}_{it})^2 \\ & + \pi_6(\text{Mins}_{Z,it}) + \pi_7(\text{Goals}_{it}^*) + \pi_8(\text{Assists}_{it}^*) \\ & + \pi_9(\text{Red}_{it}) + \pi_{10}(\text{Yellow}_{it}) \\ & + \epsilon_{tij} \end{aligned}$$

where $\epsilon_{tij} \sim N(0, \sigma_\epsilon^2)$.

Level 2a: Player Model (Time-Invariant Traits)

The player-club intercept (π_{0ij}) is determined by static physical and demographic characteristics, citizenship status relative to the club, and a player-specific random effect:

$$\pi_{0ij} = \beta_{0j} + \gamma_1(\text{Height}_i) + \gamma_2(\text{Citizen}_{ij}) + \sum_p \gamma_p \mathbb{1}_{\text{Position}_i=p} + \sum_r \gamma_r \mathbb{1}_{\text{Region}_i=r} + u_{0i}$$

where $u_{0i} \sim N(0, \sigma_u^2)$.

Level 2b: Club Model (Contextual Effects)

The club-level baseline (β_{0j}) and the linear time slope (π_{1j}) are modeled as functions of club internationalization and club-specific random effects:

$$\beta_{0j} = \delta_{00} + \delta_{01}(\text{Foreign}_{tj}) + v_{0j}$$

$$\pi_{1j} = \delta_{10} + v_{1j}$$

$$\pi_2 = \delta_{20} \quad (\text{fixed across clubs})$$

$$\pi_3 = \delta_{30} \quad (\text{fixed across clubs})$$

where $\begin{pmatrix} v_{0j} \\ v_{1j} \end{pmatrix} \sim N(\mathbf{0}, \Sigma_{club})$, with $\Sigma_{club} = \begin{pmatrix} \sigma_{v_0}^2 & \sigma_{v_0 v_1} \\ \sigma_{v_0 v_1} & \sigma_{v_1}^2 \end{pmatrix}$.

Interpretation of Cross-Classification:

Player effects (u_{0i}): Capture persistent individual heterogeneity (e.g., reputation, marketability) that follows a player across clubs.

Club effects (v_{0j}, v_{1j}): Capture the baseline prestige and temporal trajectory of the club itself, which affects all players on the roster.

Cross-classified structure: A player's market value at time t depends on both their intrinsic "brand" (u_{0i}) and the club they are currently with ($v_{0j} + v_{1j} \cdot \text{Year}_t$).

4 Results

Model Building and Comparison

We fitted a series of nested multilevel models to identify the optimal specification. We started with a null model containing only random intercepts for players and clubs to establish baseline variance partitioning. We then systematically added temporal trends (linear, quadratic, and cubic), random slopes for club trajectories, player-level predictors, and finally club-level contextual factors. We compared models using likelihood ratio tests (LRT) with REML estimation and assessed fit using AIC and BIC criteria.

Market Evolution (RQ1)

Our model reveals a significant cubic trend ($p < .001$) in market evolution. As shown in Figure 6A, the market followed an S-shaped trajectory. We observed stagnation from 2013 to 2014, followed by a rapid inflationary boom from 2015 to 2019, and then a post-2020 plateau. This confirms that football market inflation is cyclical rather than constant.

Biological Career Arc (RQ2)

We observe a strong quadratic effect for age ($p < .001$). Figure 6B illustrates the inverted-U shape, where value peaks during a player’s prime (approximately age 27) and declines significantly in the veteran stage.

Squad Status Premium (RQ3)

Our results show that squad status is a massive driver of valuation. Because we standardized minutes played, the coefficient (approximately 0.35) indicates that a one standard deviation increase in playing time is associated with a 42% increase in market value. This confirms that being a starter is financially distinct from being a rotation player.

Contextual Effects (RQ4)

We find evidence of a diversity premium. A 10 percentage point increase in a club's foreign player proportion increases average player value by 2%. Conversely, we find a domestic discount where homegrown citizens are valued 17% lower than foreign imports.

5 Club-Level Heterogeneity

Figure 7 displays the estimated club random effects from our cross-classified model. We find substantial heterogeneity in both baseline valuations and temporal trajectories.

Figure 2: Key drivers of market value. Panel A shows the cubic market trend over time. Panel B displays the quadratic career arc with peak around age 27. Panel C illustrates the squad status premium for starters. Panel D demonstrates the diversity premium for international rosters.

5.1 Baseline Premiums and Discounts

Manchester United exhibits the largest effect. When controlling for age, position, and performance, United players are valued 68% higher than league average. The 95% confidence interval ranges from 31% to 76%. Barcelona shows a 56% premium (95% CI from 29% to 93%), while Paris Saint-Germain shows a 26% premium (95% CI from 6% to 53%). Chelsea, Manchester City, and Bayern Munich also show significant premiums of approximately 22% to 25%.

Conversely, seven clubs show significant discounts. Sevilla faces the steepest penalty, with players valued 28% below league average (95% CI from -42% to -23%). Porto shows a 27% discount, Benfica shows 22%, Roma shows 21%, Napoli shows 17%, Villarreal shows 16%, and Tottenham shows 14%.

5.2 Diverging Temporal Trajectories

Our random slopes reveal that club fortunes diverged over the study period. Three clubs showed significantly faster appreciation than league average. Arsenal showed growth of 2.9% per year (95% CI from 0.8% to 5.0%), Liverpool showed 2.7% per year (95% CI from 0.7% to 4.8%), and Tottenham showed 2.8% per year (95% CI from 0.8% to 4.8%). These trajectories coincide with improved sporting performance and, for Liverpool, a Champions League victory in 2019.

Four clubs experienced significantly slower growth or faster decline. Manchester United declined 2.8% per year (95% CI from -4.5% to -1.0%), Borussia Dortmund declined 2.3% per year (95% CI from -4.1% to -0.4%), Juventus declined 2.3% per year (95% CI from

-4.1% to -0.5%), and Barcelona declined 1.8% per year (95% CI from -3.5% to -0.1%).

Despite high baseline premiums, these clubs saw their market advantages erode over time.

6 Findings

Our study demonstrates that player market value is driven primarily by individual reputation and squad status, but is significantly moderated by club context and market cycles.

Our cross-classified approach reveals that 78% of variance can be attributed to persistent player effects while accounting for dynamic club contexts.

While our cross-classified model demonstrates strong predictive power (R-squared approximately 0.89), several limitations warrant consideration. First, although the likelihood ratio test supported including random slopes for club trajectories, we should interpret the variance estimates with caution given the relatively small number of unique clubs ($N = 21$). Second, our diagnostic plots indicated deviations from normality in the extreme tails of the residual distribution. While our large sample size ($N = 7,023$) ensures robust estimation of fixed effects, future iterations could employ robust standard errors or a Gamma GLMM to better address these extremes. Finally, predictors such as minutes played are likely endogenous, since better players naturally accrue more playing time. We should interpret our estimates as associations reflecting squad status rather than purely causal effects.

Ultimately, our research highlights the necessity of moving beyond static, single-level analyses to capture the true complexity of the football transfer market. By rigorously modeling the cross-classified intersection of individual player trajectories and dynamic club contexts, we provide a more accurate lens for valuing talent in a hyper-inflated economy. As the industry continues to professionalize, such multidimensional frameworks (which account for the interplay of human capital, institutional prestige, and market cycles) will remain indispensable for clubs seeking to distinguish genuine value from market noise.
